Abstract. We summarize the status of art of the secular evolution of low mass X-ray binaries (LMXBs) and take a close look at the orbital period distribution of LMXBs and of binary millisecond pulsars (MSP), in the hypothesis that this latter results from the LMXB evolution. The deficiency of systems below the period gap, which in cataclysmic binaries occurs between ~ 2 and 3 hr, points to a very different secular evolution of LMXBs with respect to their counterparts containing a white dwarf compact object. The presence of several ultrashort period LMXBs (some of which are also X-ray millisecond pulsars), the important fraction of binary MSPs at periods between 0.1 and 1 day, the periods (26 and 32hr) of two “interacting” MSPs in Globular Clusters are other pieces of the puzzle in the period distribution. We consider the possible explanations for these peculiarities, and point out that Grindlay’s old proposal that all (most of) LMXBs in the field were originally born in globular clusters must be carefully reconsidered.

Keywords: stars: millisecond pulsars, low mass X-ray binaries, globular clusters

INTRODUCTION

We re-examine the secular evolution of low mass X ray binaries (LMXBs) and its possible remnant population, the millisecond pulsars (MSP) both in the field and in Globular Clusters (GCs). In particular we pay attention to the possible effects of a “radio-ejection” phase, initiated when the mass transfer temporarily stops during the secular evolution.

The fraction of binary MSPs and LMXBs in GCs is much larger with respect to the fraction in the galactic field. This is regarded as a clear indication that binaries containing neutron stars (NS) in GCs are generally not primordial, but are a result of stellar encounters due to the high stellar densities in the GC cores. On the other hand, it is still not clear how the LMXBs are formed in the galactic field. In fact, the supernova explosion in a binary in which the companion is a low mass star will generally destroy the binary. Possible paths have been suggested to explain the survival of LMXBs in the field:

1. accretion induced collapse of a white dwarf primary into a neutron stars [12, 5];
2. supernova “kicks” due to asymmetric neutrino energy deposition during the supernova event [16];
3. a large fraction of today’s LMXBs could have started their life as intermediate mass X-ray binaries (IMXBs) stars, with donors initially as massive as $2-3M_{\odot}$ [21];

4. LMXBs were formed by capture in the dense environment of Globular Clusters which, later on, were destroyed, and the binary remains isolated in the galactic field or bulge [14].

This latter hypothesis, originally proposed by Grindlay in 1984, was recently re-appraised by Podsiadlowski et al. [21] and is also proposed in this talk, based on some evidence coming from the period distribution of LMXBs. Further observations in favour of this hypothesis, for early type galaxies, comes from the finding that the ratio of the global LMXB X-ray luminosity to galactic optical luminosity in elliptical galaxies is strongly correlated with the specific globular cluster frequency in ellipticals [30, 17]. A general discussion of the origin of LMXBs in external galaxies is given in [9].

In the following we examine both the evolution above and below the “bifurcation period” P_{bif} [29, 22] and discuss what we can infer from the comparison of the resulting orbital period distributions with the observed ones.

EVOLUTION STARTING AT $P > P_{\text{bif}}$

The “standard” secular evolution of LMXBs as progenitors of binary MSPs finds a reasonable application to the evolution of binaries above the so called “bifurcation period” P_{bif} [29, 22], in which the donor stars begins the mass transfer phase after it has finished the phase of core hydrogen burning, and the system ends up as a low mass white dwarf (the remnant helium core of the donor) in a relatively long or very long orbit with a radio MSP (e.g. [23]). Some of these systems may also be the remnant of the evolution of intermediate mass donors, with similar resulting orbital periods, see, e.g., [21]. Recently, [6] we have shown that the secular evolution at $P > P_{\text{bif}}$ may need to take into account the detailed stellar evolution of the giant donor, to explain the orbital period gap of binary MSPs between ~ 20 and ~ 60 days. During the evolution along the RGB, the hydrogen burning shell encounters the hydrogen chemical discontinuity left by the maximum deepening of convection [28]. The thermal readjustment of the shell causes a luminosity and radius drop, which produces a well known “bump” in the luminosity function of the red giant branch in globular clusters [11, 31]. In semi detached binaries, at the “bump”, the mass transfer has a temporary stop, due to the sudden decrease of the radius. When the radius increases and the mass transfer starts again, we consider possible that a phase of “radio-ejection” begins ([2, 3]), in which mass accretion on the neutron stars is not allowed due to the pressure exerted by the radio pulsar. In this case, the matter is lost from the system at the inner lagrangian point, carrying away angular momentum and altering the period evolution. This will occur especially for magnetic moments of the NS in a range $(2 \times \lesssim \mu \lesssim 4) \times 10^{26} \text{Gcm}^3$, which is the most populated range for binary MSPs. If this is the explanation, we predict that the magnetic moments of binary MSPs which can be eventually found in the period gap at 20–60 days should be preferentially either smaller or larger than the range quoted above.

FIGURE 1. The evolutions in the plane P_{orb} vs. age for donors of $1.2M_{\odot}$, $Z=0.01$ starting mass loss from different initial P_{orb} , and thus different degrees of hydrogen consumption in the stellar core. The dots indicate phases at which mass transfer stops. If present, the following dot along the same evolution indicates where mass transfer resumes. The scarcely evolved sequences (those starting from the shorter P_{orb}) all show a more or less wide period gap at 2–3hr. The more evolved sequences do not show a period gap and reach very short P_{orb} : these can explain the ultra–short period LMXBs at $P_{\text{orb}} \sim 40\text{m}$. Two among the even more evolved sequences detach at $P_{\text{orb}} \lesssim 6\text{hr}$, so that they can resume mass transfer within the Hubble time, and go down to the shortest P_{orb} systems (11 and 20m). The others detach at the intermediate periods below ~ 1 day where many binary MSPs are found.

EVOLUTION STARTING AT $P < P_{\text{bif}}$

If the secular evolution of LMXBs below P_{bif} is similar to the evolution of cataclysmic binaries (CBs), we should expect many systems at $P \lesssim 2$ hr, and a minimum orbital period similar to that of CBs, namely ~ 80 minutes. On the contrary, there are very few of these systems, and there are several “ultrashort” binaries. In particular, three LMXBs in the field (which are also X–ray MSPs) and one in a Globular Cluster (XB 1832-330 in NGC 6652 [7]) are concentrated in the range $44 \lesssim P_{\text{orb}} \lesssim 40$ minutes [18, 13, 19]. In addition there are two other ultrashort systems in Globular Clusters (XB 1850-087 in NGC 6712 at $P_{\text{orb}}=20.4\text{m}$ and XB 1820-303 in NGC 6624 at $P_{\text{orb}}=11.4\text{min}$). While for the systems in GCs we may think that they were formed by capture of a white dwarf by the neutron star, the systems in the field should have reached this phase by secular evolution. Models have been built up [20, 21], that imply that the donors began Roche lobe overflow at periods *just a bit* below P_{bif} , so that the donor evolved to become a degenerate dwarf predominantly composed of helium, but having a residual, very small ($<10\%$) hydrogen abundance. Until hydrogen is present in the core of the donor star, in fact, the evolution proceeds towards short P_{orb} (convergent systems). The mass radius

FIGURE 2. Number vs. period distribution expected for LMXBs, by applying a population synthesis analysis based on a library of evolutions similar to those presented in Figure 1. The analysis is from [24].

relation when these objects are close to degeneracy, if the hydrogen content left is very small, is intermediate between that of hydrogen dominated brown dwarfs and that of helium white dwarfs, so that smaller radii and shorter P_{orb} will be reached before radius and period begin increasing again. One problem of this scenario is that *there is a very small interval of initial P_{orb}* which allows this very peculiar evolution: in most cases, either a helium core is already formed before the mass transfer starts, and the system evolves towards long P_{orb} , or there is enough hydrogen that the system is convergent, but the minimum period is similar to that of CBs, and can not reach the ultrashort domain (see also [27]). This is shown in Figure 1 [24], where the evolutions for a donor of $1.2M_{\odot}$, metallicity $Z=0.01$ in mass fraction, are shown for increasing starting periods for the mass loss phase.

Podsiadlowski et al. [21] notice that, for a $1M_{\odot}$ secondary, the initial period range 13–18 hr leads to the formation of ultracompact systems. Since systems that start mass transfer in this period range are naturally produced as a result of tidal capture, this may explain the large fraction of ultracompact LMXBs observed in globular clusters. This however does not apply to LMXBs in the field. In her PhD thesis, A. Teodorescu [24] built the number vs. period distribution expected for LMXBs for convergent systems under several hypotheses, and compared it with the available observed period distribution. An expected result was that the range $P_{\text{orb}} < 2\text{hr}$ is very populated (Figure 2) and the distribution is inconsistent with observations, *unless we can suppress the secular evolution of all the systems below the “period gap”* which occurs at about the same location as in CBs, as shown in Figure 1. We can explore several different possibilities to do this:

FIGURE 3. In the bottom figure we show the possible evolutions for the companion of PSR J1740-5340. All tracks start close to the turnoff of a $M=0.85M_{\odot}$, when hydrogen is almost fully depleted in the central regions. The continuous line evolving to the longest periods is the conservative evolution considered in [3]. The curve passing through the square indicating the observed mass of the donor shows the evolution obtained by assuming that, starting at a period of ~ 26 hr, the mass is lost from the system with the specific angular momentum of the donor star. The other curves starting from the same $P=26$ hr represent evolutions with different amounts of loss of specific angular momentum. The top figure shows similar evolutions starting from a donor of $1.1M_{\odot}$, aimed to interpret the evolutionary status of the donor of PSR J1748-2446ad in the GC Terzan 5. A solar chemistry is assumed here, close to the metallicity of this cluster. The donor mass is not observationally constrained here, but it looks evident again that the evolution of the donor must have started close to the bifurcation period.

1. It is possible that the lack of P_{orb} 's < 2 hr is again an effect due to radio-ejection: after the period gap is traversed by the detached system, when the mass transfer resumes, accretion is prevented by the pulsar pressure, the matter escapes from the system with high specific angular momentum, and the evolution is accelerated. This is possibly occurring in the system containing the radio pulsar PSR J0024.7204W in the GC 47 Tuc, at $P_{\text{orb}}=3.2$ hr. This system exhibits X-ray variability which can be explained by the presence of a relativistic shock within the binary that is regularly eclipsed by the secondary star [1]. The shock can then be produced by the interaction of the pulsar wind with a stream of gas from the companion issuing through the inner Lagrange point (L1), a typical case of what is intended by radio-ejection [2]. This mechanism could affect all the systems which enter a period gap. Notice that only systems which end up at ultra-short periods *do not* detach during the secular evolution: is this the reason why they are so prominent in the number vs. period distribution? In the framework of this explanation, both the lack of systems at $P_{\text{orb}} < 2$ hr and the presence of ultrashort periods would be due to this effect.

2. “Evaporation” of the donor, due to the the pulsar wind impinging on, and evaporating material off of the surface of the companion (e.g, [25]) is another possible mechanism. The difference with respect to the previous case is that evaporation is effective also during the phase in which the system is detached.
3. It is possible that the secular evolution practically never begins when the donor is not significantly evolved. This can be true only if binaries are mostly formed by tidal capture, in which the NS captures a main sequence object only at separations $1.5R_* \lesssim a \lesssim 3R_*$ [10], as it may happen in GCs, but we are examining the P_{orb} distribution of *all* the LMXBs in the Galaxy. We should then *re-appraise Grindlay’s suggestion that most of the field LMXBs were formed in GCs, which were later on destroyed* by tidal interactions with the galactic bulge.

At the time of writing up this talk, we still have the opinion that the provocative issue that most LMXBs were actually born in GCs must be considered again in more detail.

EVOLUTION STARTING AT P VERY CLOSE TO P_{bif}

There are other cases which show us that some evolutions start very close to P_{bif} : the famous interacting MSP binary in NGC 6397, PSR J1740-5340 is such a case: at $P_{\text{orb}}=35.5$ hr, it seems to be in a radio-ejection phase [3]. Surely the companion has not been captured recently by stellar encounters: it is an evolved subgiant, as predicted by the secular evolution models [3], and as testified by the CN cycled chemistry of the donor envelope [26], and predicted by Ergma & Sarna [8]. We suggest that also PSR J1748-2446ad, the fastest spinning MSP discovered in the Globular Cluster Terzan 5 [15] is in a radio-ejection phase [4], but the lack of information on the donor preclude a very secure interpretation. At $P_{\text{orb}}=26.26$ hr, again, the donor should be in an early subgiant stage, and have evolved very close to P_{bif} . In Figure 3 we show the possible period evolution for the companion of PSR J1740-5340, which must be indeed very slightly evolved off the main sequence in order to fit the orbital period and the donor mass very well determined from observations, and the possible evolutionary paths for the donor of PSR J1748-2446ad, which must be even less evolved at the beginning of mass transfer, both because the final period is shorter (26.6 hr) and because Terzan 5 has a larger metallicity than NGC 6397, so that the initial stellar radii are larger for a mass evolving in a time span of about 10^{10} yr. Unfortunately, nothing is known about the optical counterpart of this system, so that the evolution can not be determined better.

Finally, we have to remember that *the whole period distribution of binary MSPs in GCs* is consistent with a very high probability of beginning of mass exchange close to P_{bif} : in fact, there is a large group having P_{orb} from 0.1 to 1 days, a range, e.g., not covered at all by the “standard” evolutions by [21], but which results easily from the range of initial periods which are between those leading to ultrashort binaries and those above bifurcation (see Figure 1 from [24]). Finally, there are several binary MSPs in GCs for which the white dwarf mass is very low ($0.18\text{--}0.20M_{\odot}$), close to the minimum mass which can be formed by binary evolution [3], indicating again evolution starting at a period slightly larger than P_{bif} .
